Appropriate protein provision in critical illness: a systematic and narrative review1–3

L John Hoffer and Bruce R Bistrian

ABSTRACT

Background: Widely varying recommendations have been published with regard to the appropriate amount of protein or amino acids to provide in critical illness.

Objective: We carried out a systematic review of clinical trials that compared the metabolic or clinical effects of different protein intakes in adult critical illness and comprehensively reviewed all of the available evidence pertinent to the safe upper limit of protein provision in this setting.

Design: MEDLINE was searched for clinical trials published in English between 1948 and 2012 that provided original data comparing the effects of different levels of protein intake on clinically relevant outcomes and evidence pertinent to the safe upper limit of protein provision to critically ill adults.

Results: The limited amount and poor quality of the evidence preclude conclusions or clinical recommendations but strongly suggest that 2.0–2.5 g protein substrate · kg normal body weight−1 · d−1 is safe and could be optimum for most critically ill patients. At the present time, most critically ill adults receive less than half of the most common current recommendation, 1.5 g protein · kg−1 · d−1, for the first week or longer of their stay in an intensive care unit.

Conclusion: There is an urgent need for well-designed clinical trials to identify the appropriate level of protein provision in critical illness. Am J Clin Nutr 2012;96:591–600.

INTRODUCTION

The metabolic response to severe tissue injury and sepsis releases a flood of amino acids from their muscle reservoir (1) into the general circulation, enabling new protein synthesis at sites of tissue injury and elsewhere to optimize immune function and regulate the inflammatory response. The cost of this rapid body protein remodeling is anabolic inefficiency: net muscle protein loss greatly exceeds the gain of protein mass elsewhere, and whole-body nitrogen balance becomes strongly negative (2–7).

Plasma amino acid concentrations could provide insight into this process, but they vary widely in adult critical illness, being affected by the phase and intensity of the injury response; the patient’s existing nutritional, metabolic, and hemodynamic status; and the characteristics of the nutritional therapy provided. When measured in previously adequately nourished patients after successful fluid resuscitation and before exogenous nutrient provision, plasma nonessential amino acid concentrations are usually low and essential amino acid concentrations are either normal or low (8–15). But circulating amino acid concentrations show only a static view of what is a highly dynamic process. Amino acid concentrations could be increased by intense net muscle proteolysis or inadequate liver uptake and metabolism in the setting of liver hypoperfusion or metabolic failure (12, 16–18), or they could be reduced despite a high rate of release from muscle that is still insufficient to match the combined rates of central protein synthesis, gluconeogenesis, and immediate amino acid catabolism, all of which are accelerated in critical illness. By using a simple nonisotopic amino acid infusion technique, a recent study (19) confirmed the suggestions of previous, more complicated techniques (9, 14, 17, 20) that hypoaminoacidemia in severe human sepsis is the result of an ~70% increase in the clearance of essential and nonessential amino acids into the tissues.

The hypoaminoacidemia of critical illness thus appears to represent a state of increased amino acid uptake by the rapidly turning over central proteins [liver, splanchic organs, bone marrow, and immunologically active tissues (20)], which is constrained by the maximum rate of amino acid release from muscle. This is a portrayal of acute central protein deficiency, and it suggests that sufficient exogenous amino acid provision could improve clinical outcomes, both early by increasing central protein synthesis, optimizing the inflammatory response (7, 21), and mitigating the extensive loss of muscle protein characteristic of the first week of catabolic critical illness (22–24) and in the long term by minimizing the muscle atrophy that commonly occurs in protracted critical illness (22, 23). With only one exception (25), every expert review and clinical practice guideline that has addressed the question of protein requirements in critical illness has concluded that adequate protein provision is necessary to improve body protein economy in all but the most hypercatabolic and hemodynamically compromised patients, and has asserted that the amount of dietary protein required to do this exceeds the normal requirement (26). But specifically how much more protein is required? The recommendation for metabolically normal hospitalized adults is the same as for healthy people: 0.8 g of protein · kg normal body weight−1 · d−1 (27). The most common recommendation in critical illness lies between 1.2 and 1.5 g protein · kg normal body weight−1 · d−1, provided as either dietary protein or mixed free amino acids administered either

parenterally or enterally (3, 26, 28–32). By contrast, some experts (33–35), as well as the clinical care guidelines of the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN), recommend protein or amino acid intakes as high as 2.0 g/kg (36). The SCCM/ASPEN guidelines recommend 2.0 g protein/kg ideal body weight as the minimum amount to provide to severely burned and multi-trauma patients and permissively underfed obese patients and a minimum of 2.5 g/kg ideal body weight for critically ill, permissively underfed morbidly obese patients (36). The evidence-based guideline group of the American Burn Association points out, without further comment, that protein provision for severely burned patients varies from 1.5 to 3.0 g · kg\(^{-1}·d\(^{-1}\)) (37). The European Society for Enteral and Parenteral Nutrition (ESPEN) (31) recommends from 1.3 to 1.5 g · kg\(^{-1}·d\(^{-1}\)) for almost all critically ill patients, whereas the European Society of Intensive Care Medicine specifically cautions against protein intakes >1.8 g · kg\(^{-1}·d\(^{-1}\)) (29). One reviewer acknowledged the wide difference of opinion among experts without taking a position as to whether protein provision should be capped at 1.5 g · kg\(^{-1}·d\(^{-1}\)) or provided in excess of 2.0 g · kg\(^{-1}·d\(^{-1}\)) (38). The Canadian clinical practice guidelines refrain from making any recommendation about protein requirements (39).

None of these widely differing recommendations appear to be based on systematic reviews of the evidence (40). Accordingly, we carried out a systematic review of the clinical literature pertinent to the optimum and safe upper limit of protein provision in adult critical illness.

**METHODS**

The aims of the literature search were as follows: first, to identify and analyze all prospective clinical trials of any kind that compared clinically relevant consequences of providing different levels of protein or mixed amino acids to critically ill adults; and second, to analyze all of the available evidence pertinent to the safe upper limit of protein provision in critical illness.

MEDLINE was searched for clinical trials published in English between 1948 and 2012 (the last search was on 4 May 2012) that provided original data comparing the effects of different levels of protein provision to critically ill adults, as well as clinical reviews and clinical care guidelines on this topic. We accessed and studied all pertinent articles cited in the primary sources and all articles cited in reviews and clinical care guidelines to justify the protein intakes they recommended. Studies that enrolled uncomplicated surgical patients were not included. There is a metabolic continuum between surgical injury and critical illness (38, 41), but critical illness is a more serious and prolonged protein-catabolic insult than that experienced by most surgical patients. The inclusion of data from non–critically ill surgical patients could bias the data toward an underestimation of the protein requirement in true critical illness. No study was excluded on the grounds of low enrollment, even though such studies often provide only limited information (42).

For the second aim, the same search was expanded to include all articles of any kind that reported or discussed issues related to protein or amino acid excess, maximum administration, or toxicity that would be pertinent to the usual time course of critical illness. The search included any article that could be identified that described the effects of high-dose protein or amino acid administration on urea and ammonia metabolism in health or critical illness.

The MEDLINE search included the following key words relevant to critical illness: critical illness, critical care, burns, infections, inflammation, shock (including multiple organ failure, surgical shock, traumatic shock, and systemic inflammatory response syndrome), wounds and injuries, and trauma. Articles that reported clinical trials comparing the effects of different levels of protein provision were searched for by using the following key words: nutritional support, dietary proteins, proteins, amino acids, nutritional requirements, and nutritional physiologic phenomena. The intersection of these 2 topic searches yielded a large number of articles that were analyzed as to their eligibility for inclusion in a systematic review of outcomes resulting from different levels of protein or amino acid provision in adult critical illness. The small enrollment, heterogeneity, and variation in diagnosis and study design in the articles that were identified precluded their statistical combination into a meta-analysis. The literature pertinent to the upper limit of protein provision in critical illness was so vague, minimal, and poorly characterized as to require a de novo interpretative analysis.

**RESULTS**

A total of 253,519 articles were found with the following key words or MeSH terms: critical illness (MeSH term and keyword; 14,836 articles) or critical care (MeSH term and keyword 29,048) or burns/dh, me, pp, th (12,855) or infections/dh, me, th (27,130) or inflammation/dh, me, th (13,889) or shock (including multiple organ failure, surgical shock, traumatic shock, and systemic inflammatory response syndrome; 33,889) or wounds and injuries/dh, me, th (11,540) or trauma (keyword; 151,584). The terms nutritional support (including diet therapy, parenteral nutrition, and enteral nutrition; 8329) or dietary proteins/ad, me, pd, st, to, tu (20,311) or proteins/ad, ae, me, pd, ph, st, to, tu (78,286) or amino acids/ad, ae, df, me, pd, ph, st, th, to, and tu refer to administration and dosage, adverse effects, deficiency, diet therapy, metabolism, pharmacology, physiopathology, standards, therapy, toxicity, and therapeutic use, respectively.) The intersection of the 253,519 critical illness titles and the 181,915 nutritional titles yielded 3461 articles whose titles or abstracts were individually studied with regard to both aims. Of these articles, 3445 were obviously irrelevant or ineligible. Three articles whose titles or abstracts implied that they involved critically ill patients were excluded because the patients were postoperative rather than critically ill.

**Effects of varied protein intakes on outcomes in critical illness**

Only 13 articles met the inclusion criteria for the systematic review of outcomes consequent to the deliberate provision of different levels of protein or amino acids in adult critical illness (10, 43–54); they are described in Table 1. Even though it was

2 Although ineligible, this study is listed because it is one of the most frequently cited studies to justify current recommendations for protein provision in critical illness.
Upper limit of protein provision

An expert working group studied the upper limits of human protein consumption, noting that strength-training athletes sometimes consume as much as 4 g · kg\(^{-1}\) · d\(^{-1}\) without adverse consequences, and that as much as 8 g protein · kg\(^{-1}\) · d\(^{-1}\) has been given for short periods without reported ill effects (58, 59). Late paleolithic humans consumed ~250 g protein/d (60, 61). According to a recent observational study, adults with severe burns in the United States and Australia are routinely provided with 2–3 g protein · kg\(^{-1}\) · d\(^{-1}\) in the form of high-energy enteral nutrition (62).

A study in 24 acutely (but not critically) ill surgical patients compared the effects of 3 different parenteral nutrition solutions on nitrogen balance and liver protein content as measured in liver biopsies obtained before and after ~11 d of treatment (63). Two solutions provided 1.1 g amino acids and ~55 kcal · kg\(^{-1}\) · d\(^{-1}\) with different amounts of lipid, and one solution provided 3.1 g amino acids and 35 kcal · kg\(^{-1}\) · d\(^{-1}\). Nitrogen balance was equally positive with all regimens, with no indication of toxicity at the 3.1-g/kg dose. Average liver protein content (which was

patently ineligible, one retrospective observational study is included in Table 1 (55), because it is one of the most frequently cited articles in the literature on protein provision in critical illness. The clinical trials were either sequential (43, 44, 50, 51) or concurrent (10, 45, 46, 48, 49, 52–54) or both (47). They tested a variety of different protein or amino acid doses, up to a maximum of 2.5 g · kg\(^{-1}\) · d\(^{-1}\), for various periods of time. Only 4 studies (45, 48, 49, 52) were randomized; none were blinded. The outcome measures were as follows: nitrogen balance in 12 studies, aspects of whole-body protein turnover in 3 studies (44, 46, 54), change in body composition in 1 study (55), plasma amino acid profile in 1 study (51), and clinical outcomes in 2 studies (52, 53).

Every study showed at least one, and usually several, of the following weaknesses in design, execution, or interpretation: unclear definition of critical illness; low enrollment and such wide intergroup heterogeneity as to make it impossible to identify any particular level of protein provision as maximally beneficial; failure to appreciate that a nutrient intake that is adequate to prevent nitrogen balance in 12 studies, aspects of whole-body protein turnover in 3 studies (44, 46, 54), change in body composition in 1 study (55), plasma amino acid profile in 1 study (51), and clinical outcomes in 2 studies (52, 53).

Every study showed at least one, and usually several, of the following weaknesses in design, execution, or interpretation: unclear definition of critical illness; low enrollment and such wide intergroup heterogeneity as to make it impossible to identify any particular level of protein provision as maximally beneficial; failure to appreciate that a nutrient intake that is adequate to prevent negative nitrogen balance in 12 studies, aspects of whole-body protein turnover in 3 studies (44, 46, 54), change in body composition in 1 study (55), plasma amino acid profile in 1 study (51), and clinical outcomes in 2 studies (52, 53).

The SCCM/ASPEN recommends that all hypocalorically fed, critically ill, obese patients receive between 2 and 2.5 protein · kg\(^{-1}\) ideal body weight · d\(^{-1}\) (36). This recommendation appears to be based on a small number of low-enrollment clinical trials that have been formally reviewed so often that the number of published reviews (36, 56, 65–80) now exceeds the number of original research reports. It is sufficient for the purposes of this review to summarize those aspects pertinent to the upper limit of protein provision. Most, but not all (81–83), hypocaloric, high-protein clinical trials enrolled patients who were critically ill, and most, but not all, enrolled obese patients. Only 3 reviews (75, 78, 80) distinguished between “hypocaloric nutrition” (selective energy restriction with a compensatory increase in protein provision) and “permissive underfeeding” (global underprovision of all nutrients) despite the profoundly different physiologic and nutritional implications of these different nutritional regimens. Every review concluded that short-term hypocaloric nutrition is scientifically plausible, because it is supported by metabolic indicators and limited but promising clinical outcome data, but awaits definitive testing.

Only one clinical trial appears ever to have been carried out to determine the protein requirement of hypocalorically fed, hospitalized patients. Greenberg and Jeejeebhoy (81) randomly assigned non–critically ill, nonobese patients (described as having adequate fat stores) to receive, as their sole nutrition, either 0.83 or 1.83 g amino acids · kg ideal body weight · d\(^{-1}\). Nitrogen balance of the patients who received 0.83 g amino acids/kg ideal body weight was consistently negative, whereas that of those who received 1.83 g was positive (81).

Most reviews of hypocaloric nutrition, and the SCCM/ASPEN guidelines (36), either explicitly or implicitly assert that the more favorable metabolic and clinical outcomes attributable to hypocaloric feeding may rely on their generous protein provision. This reasoning underlies the current SCCM/ASPEN recommendation that hypocalorically fed, obese patients receive a minimum of 2.0 g protein · kg ideal body weight · d\(^{-1}\) · d\(^{-1}\). A clinical trial that compared different protein intakes in the treatment of protein-energy malnutrition (84) was cited as indicating that high protein intakes are dangerous (25). Collins et al. (84) provided either 2.4 or 4.6 g protein · kgideal body weight · d\(^{-1}\) to severely malnourished adults (average weight: 34 kg) in a famine zone. The higher protein dose was associated with worse outcomes in the subset of patients suffering from edematous malnutrition. However, clinical outcomes were similar with either treatment in the nonedematous patients who accounted for the majority of the patients, and correction for biased treatment allocation could well eliminate the adverse effect attributed to the higher protein dose in the edematous patients (85). For the majority of these severely malnourished adults, the so-called low-protein dose of 2.4 g protein · kg\(^{-1}\) · d\(^{-1}\) was well tolerated by all patients, and their clinical outcome was favorable (84).
The most obvious way that protein can be toxic is by generating ammonia in excess of the urea cycle’s capacity. Rudman et al (86) determined the maximum rate of liver urea synthesis in 10 healthy adults and 34 patients with stable cirrhosis, no ascites, and normal renal function. After consuming a basal diet containing 0.7 g protein · kg⁻¹ · d⁻¹, volunteers were provided with single- or divided-protein meals containing from 0.57 to 2.86 g protein/kg. This study indicated that a healthy adult can convert 3.8 g protein/kg into urea per day. The maximum urea synthetic rate in persons with stable cirrhosis was approximately one-half that rate, with very wide variability. The metabolic indicators of protein intolerance were hyperaminoacidemia and hyperammonemia.

Hyperammonemia and encephalopathy are well-known complications of protein or amino acid provision to patients with severe liver dysfunction (87) and a rare but well-documented complication of dietary protein or parenteral amino acid provision to previously asymptomatic adults with heterozygous ornithine transcarbamoylase deficiency (88) or other urea cycle disorders (87, 89). Severe hyperammonemia has been reported in patients with previously normal liver function who underwent an orthotopic lung transplantation (90); the etiology is multifactorial. Importantly, moderate hyperammonemia, seldom greater than 100 μmol/L (91), has been described in previously asymptomatic adults with heterozygous ornithine transcarbamoylase deficiency (88) or other urea cycle disorders (87, 89). Severe hyperammonemia has been reported in patients with previously normal liver function who underwent an orthotopic lung transplantation (90); the etiology is multifactorial, and parenteral amino acid provision is one risk factor (91).

In 1977 Hackl et al (92) reported that after a week of parenteral amino acid administration, which provided 0.8–1.6 g amino acids · kg⁻¹ · d⁻¹ to 47 patients, most of whom were critically ill, blood ammonia concentrations increased in every patient to an average maximum value of ∼110 μmol/L, with a modest downward trend thereafter. There was no correlation with serum urea concentrations nor with serum alkaline phosphatase or glutamic oxaloacetic transaminase concentrations. The clinical implication of these observations is unclear, especially because early commercial amino acid solutions were contaminated with ammonia (93, 94).

Patients with overwhelming critical illness and hepatic hypoperfusion develop hyperaminoacidemia (9, 16, 17), even in the absence of amino acid infusions (18). Sprung et al (18) compared plasma amino acid and ammonia concentrations in severely infected but hemodynamically stable patients and septic hypotensive patients with an altered sensorium. Amino acid concentrations were markedly higher in the hypotensive group (especially the aromatic amino acids, which are catabolized only in the liver). Average plasma ammonia concentrations were above normal in the normotensive patients (127 μmol/L) but were substantially higher in the hypotensive patients (425 μmol/L). Almost nothing is known about the prevalence and severity of asymptomatic hyperammonemia or orotic aciduria (95) in critically ill patients with normal or mildly abnormal hepatic function, nor on the effects of dietary protein or mixed amino acid infusions in these patients.

Amino acid infusions limited to the essential amino acids can induce hyperammonemia in children and, more rarely, in adults (96, 97), presumably because they lack arginine (93, 98). By comparison, the molar fraction of arginine in modern complete parenteral amino acid mixtures is ∼60% greater than in dietary proteins (57). Mild hyperammonemia has been reported to be relatively common in infants infused with complete amino acid mixtures (94) and is more likely when high doses are administered shortly after birth. Thus, 6 of 30 very-low-birth-weight infants infused with 4 g amino acids · kg⁻¹ · d⁻¹ shortly after birth experienced mild elevations in blood ammonia (97–127 μmol/L) (99).

Some reviewers regard an abnormally increased serum urea concentration (azotemia) as evidence of amino acid toxicity (34, 35, 100); one expert specifically regards a serum urea concentration >80 mg/dL (30 mmol/L) as undesirable (101). Mechanisms by which simple azotemia could be harmful or increase risk have not been articulated, however. The rate of amino acid oxidation (and corresponding urea synthesis rate) is increased in critical illness (102), and although urea synthesis is strongly influenced by the rate of protein provision, circulating urea concentrations are far more greatly influenced by renal blood flow and renal parenchymal functional mass than by the protein provision rate (103). Thus, Twyman et al (45) observed that the administration of 2.2 g protein · kg⁻¹ · d⁻¹ led to greater nitrogen excretion (and more positive nitrogen balance) than did 1.5 g protein · kg⁻¹ · d⁻¹, but there were similar serum urea concentrations. Singer et al (53) compared the metabolic effects of providing either 75 or 150 g parenteral amino acids/d to critically ill patients with nonoliguric renal failure who were not receiving renal replacement therapy. Baseline serum urea concentrations (~50 mg/dL) increased by 30% (to 59 mg/dL) when 75 g amino acids/d was provided and by 22% (to 64 mg/dL) when 150 g was provided. Clinical outcomes were superior in the patients who received 150 g/d.

On balance, the available evidence indicates that protein provision in doses between 2.5 and 3.0 g/kg normal body weight per day are safe for use in clinical trials and careful clinical practice, except in patients with refractory hypotension, overwhelming sepsis, or serious liver disease. The determination as to when a particular patient has refractory hypotension, overwhelming sepsis, and serious liver disease is based on clinical judgment; no specific information is available to guide the choice of any protein or amino acid dose in these situations.

DISCUSSION

The prevalent opinion in modern critical care nutrition is that 1.2–1.5 g protein · kg normal body weight⁻¹ · d⁻¹ is sufficient—and hence not usually to be exceeded (26). This widespread opinion appears to be based on the biased selection of a small and unrepresentative subset of low-quality studies published between 14 and 36 y ago that enrolled critically ill, energy-overfed patients. These studies are praiseworthy for their innovative and ambitious design and execution and for the physiologic insight they provided. It is noteworthy that every study suggested that insufficient protein provision leads to serious and preventable body protein wasting. Notwithstanding claims made by some of their authors, no study was sufficiently powered to rule in or out any specific protein or amino acid intake as maximally beneficial. Several other problems are apparent.

First, no author appreciated that a level of nutrient intake that is adequate on average is, by definition, insufficient for half of a population whose data are symmetrically distributed. The correct procedure is to calculate an allowance for individual variability to arrive at a “safe” recommended intake. Second, protein intakes were based on body weight, but in every study except for one (55), the investigators failed to explain how they determined body weight. In critical illness even accurately measured body weight is an extremely unreliable surrogate for
the biologically relevant variable, lean tissue mass (24, 56). Third, the majority of patients were deliberately energy overfed as a tactic to maximize body nitrogen retention. The protein requirement of patients in energy equilibrium or negative energy balance could be considerably higher. Fourth, the majority of studies (17, 44, 46, 55) calculated amino acid dosages as though they are equivalent to formed protein, but they are not: free amino acid mixtures provide 17% less protein substrate than does formed protein (57). Other studies used the conventional factor 0.16 to convert amino acid nitrogen to its protein equivalent; this factor does not apply to free amino acid mixtures (57).

The main conclusion of this systematic review is that nitrogen balance improves with increasing protein provision up to the highest studied dose of $2.5 \text{ g} \cdot \text{kg}^{-1} \cdot \text{d}^{-1}$. Some studies suggest that higher levels of protein provision increase the rate of whole-body protein synthesis (104, 105). How valid are these conclusions? The nitrogen balance measurement provides important physiologic insight and practical clinical guidance, but it is technically difficult and susceptible to random and systematic errors (106, 107). Nitrogen balance measurements, especially in the ambulatory setting, could be prone to overestimate nitrogen balance at high protein intakes (108), although this is by no means a universal observation (47, 48, 63, 109).

In fact, as has been frequently pointed out, it is strongly biologically plausible that sufficiently generous protein provision in the crucial early days of critical illness could improve clinical outcomes, even in the absence of any measured improvement in nitrogen balance or whole-body protein synthesis (5, 7, 31, 63). During the early phase of critical illness, the body’s priority is central protein synthesis at the expense of protein loss from the skeletal muscle compartment, which normally accounts for ~80% of the total lean tissue mass (1). Exogenous protein could increase protein synthesis in the small, but crucial, central compartment, with benefit to the patient, without necessarily requiring a commensurate reduction in muscle protein catabolism. Nitrogen balance is simply too crude a measurement to capture this and other related metabolic phenomena. For example, the protein turnover literature summarized earlier broadly suggests that in critical illness glucose infusions mitigate body nitrogen loss largely by stimulating insulin release and by inhibiting muscle proteolysis. By contrast, sufficient protein provision (up to the requirement level) mitigates nitrogen loss by promoting central and peripheral protein synthesis. The latter scenario is clearly preferable when the body’s priority is to mobilize peripheral amino acids in support of central protein synthesis. Thus, sufficient amino acid provision increases central and peripheral protein synthesis, improving nitrogen balance in the process, whereas dextrose with insufficient protein improves nitrogen balance by inhibiting muscle proteolysis and thereby inhibiting the transfer of amino acids from muscle to crucial sites of central protein synthesis, with potential harm to the patient (110).

A more important problem, with both nitrogen balance and protein turnover, is that they are surrogate outcomes that can, at most, provide provisional, hypothesis-generating conclusions. Biological and surrogate indicators such as nitrogen balance and protein turnover are essential for gaining insight into physiologic processes, identifying the causes of metabolic and clinical heterogeneity, establishing biologically plausible therapeutic hypotheses, and designing clinical outcome trials intelligently. But it is incorrect to substitute them for clinical outcomes in clinical practice guidelines, as is currently the practice (111–113). To date, the only high-quality clinical-outcome clinical trials that evaluated the effects of different protein intakes in critical illness have been in children (114–116); they indicate better outcomes with higher levels of protein provision.

The virtually complete absence of high-quality data on protein requirements in critical illness in adults is especially troubling in light of the fact that in modern times, the typical critically ill patient is fed exclusively by the enteral route and consequently is substantially undernourished for the first week or longer of treatment in an intensive care unit (ICU) (117–120). The ESPEN guidelines address this problem by recommending that parenteral nutrition be commenced within 2 d of admission to an ICU when enteral nutrition is failing to achieve its target. By contrast, the SCCM/ASPEN (36) and Canadian (39) guidelines recommend tolerating a “permissively underfed” state for up to 10 days before resorting to parenteral nutrition, except in the presence of pre-existing malnutrition (117).

The phenomenon of underfeeding by enteral nutrition is commonly described as a “calorie” shortfall (121, 122); it is more biologically coherent to describe it as a protein shortfall (21). The magnitude of the problem was recently shown by a large clinical trial, which compared the clinical consequences of following the ESPEN or the SCCM/ASPEN recommendations (123). When the SCCM/ASPEN recommendation was implemented, daily median protein provision never exceeded ~0.1 g/kg normal body weight for the entire 15-d observation period. The patients in this treatment arm received less than one-tenth of the commonest recommended amount of protein, at precisely the time when generous protein provision could be most beneficial. When the ESPEN recommendation was implemented (enteral nutrition supplemented by increasing intravenous glucose for 2 d, followed by standard parenteral nutrition), median parenteral amino acid provision had barely risen to ~0.7 g · kg$^{-1} \cdot \text{d}^{-1}$ by the seventh day in the ICU. Because 0.7 g free amino acids provides ~0.6 g protein substrate (57), these data indicate the following: first, that despite the use of parenteral nutrition, amino acid provision was grossly inadequate throughout the first 7 d in the ICU; and second, that median all-source protein provision never exceeded ~0.7 g/kg on any day during the entire 15-d observation period. The patients in this arm received less than half the current average protein recommendation, and most patients possibly received only a third or less of their individual requirement. Protein provision that is as grossly deficient as this could be well below the minimum necessary to detect any clinical benefit. Another large recent clinical trial of intensive insulin therapy in critical illness failed to provide any analyzable information about protein intake (124). On the basis of the low amount of energy provided, it appears that the patients enrolled in the trial were even more seriously protein malnourished than those in the ESPEN-SCCM/ASPEN trial (123).

The time is long overdue to launch thoughtfully designed and appropriately targeted prospective clinical trials to test the hypothesis that early and sufficient amino acid supplementation of inadequate enteral nutrition can improve the clinical outcome of many critically ill patients. Certain pitfalls will have to be avoided when designing these studies. Patients who are not critically ill should not be enrolled, because they might require no...
more than 0.8 g protein · kg⁻¹ · d⁻¹. Patients with borderline liver function should be excluded until more information on tolerance is available. Patients who have refractory hypotension or overwhelming sepsis should be excluded, because very large amounts of protein are unlikely to reverse their clinical course and could be toxic. Criteria for excluding such patients need to be developed. Critically ill patients with increased urinary urea excretion (125) and hypoaminoacidemia would seem to be the most suitable for enrollment in initial, dose-finding phase 2 clinical trials. Because protein intake calculations are based on body weight—an unreliable surrogate for lean tissue mass in critical illness (126–129)—it will be essential to use an explicit, practical rule for estimating a patient’s body weight corrected for volume expansion and excess adipose tissue.

In conclusion, the limited amount and poor quality of the available evidence preclude conclusions or clinical recommendations but strongly suggest that 2.0–2.5 g protein substrate · kg normal body weight⁻¹ · d⁻¹ is safe and could be optimum for most critically ill adults. At the present time, most critically ill adults receive less than half the commonest current recommendation, 1.5 g protein · kg⁻¹ · d⁻¹, for the first week or longer of their ICU stay. There is an urgent need for well-designed clinical trials to identify the appropriate level of protein provision in critical illness.

The authors’ responsibilities were as follows—LJH and BRB: separately reviewed the literature and prepared individual manuscripts, which LJH merged. Both authors then agreed on the systematic search criteria, which LJH executed, and the results of which both authors used to prepare the final manuscript. There were no conflicts of interest.
